## Abstract

Using a general hierarchical model we estimated relative efficiency of chain sweep to the rockhopper sweep used by the NEFSC bottom trawl survey for from studies carried out between 2015 and 2017 aboard the F/V Karen Elizabeth twin-trawl vessel. Aside from the sweeps, the rest of the trawl gear is the same. We compared a set of models with different assumptions about variation of relative efficiency between paired gear tows, size and diel effects on the relative efficiency, and extra-binomial variation of observations within paired gear tows.

Using a general hierarchical model we estimated relative efficiency of chain sweep to the rockhopper sweep used by the NEFSC bottom trawl survey for winter and windowpane flounder stocks and red hake stocks from studies carried out between 2015 and 2017 aboard the F/V Karen Elizabeth twin-trawl vessel. Aside from the sweeps, the rest of the trawl gear is the same. We compared a set of models with different assumptions about variation of relative efficiency between paired gear tows, size and diel effects on the relative efficiency, and extra-binomial variation of observations within paired gear tows. Diel effects provided improved model performance for all three species. We used the best performing model to make annual chain sweep-based swept area biomass and abundance-at-length estimates. We estimated uncertainty in all results using bootstrap procedures for each data component.

# 1 Introduction

Paired-gear studies have long been used to estimate the efficiency of one fishing gear relative to another (e.g., Gulland (1964); Bourne (1965)). These types of studies are critical for informing abundance time series from fishery independent surveys when there are changes in the vessel and(or) gears over time due to gear failures or improved technology.

In conducting paired-gear studies it is ideal to have the two gears deployed as close together spatially and temporally as possible to reduce variation between the gears in densities of the species being captured. One fishing method that approaches this ideal is the twin-trawl rigging where two trawls can be fished simultaneously (ICES 1996). The basic methods we used here are based on those used by Miller (2013) to estimate size effects on relative catch efficiency of the Henry B. Bigelow to the Albatross IV. Similar approaches were used to make similar estimates for groundfish, TRAC stocks and summer flounder (Miller et al. 2017a, 2017b). The methods here are the same as those used for red hake for the red hake research track assessments (Miller et al. 2020).

## 2 Methods

### 2.1 Data collection

Data were collected during three field experiments carried out in 2015, 2016, and 2017, respectively, aboard the F/V Karen Elizabeth, a 78ft stern trawler capable of towing two trawls simultaneously side by side. However, red hake were only observed during the 2017 field experiments. One side of the twin-trawl rig towed a NEFSC standard 400 x 12 cm survey bottom trawl rigged with the NEFSC standard rockhopper sweep (Politis et al. 2014) (Figure 1). The other side of the twin-trawl rig towed a version the NEFSC 400 x 12cm survey bottom trawl modified to maximize the capture of flatfish. The trawl was modified by reducing the headline flotation from 66 to 32, 20cm, spherical floats, reducing the port and starboard top wing-end extensions by 50cm each and utilizing a chain sweep. The chain sweep was constructed of 1.6cm (5/8in) trawl chain covered by 12.7cm diameter x 1cm thick rubber discs on every other chain link (Figure 2). Two rows of 1.3cm (1/2in) tickler chains were attached to the 1.6cm trawl chain by 1.3cm shackles (Figure 2). To ensure equivalent net geometry of each gear, 32m restrictor ropes, made of 1.4cm (9/16in) buoyant, Polytron rope, were attached between each of the trawl doors and the center clump. 3.4m<sup>2</sup> Thyboron Type 4 trawl doors were used to provide enough spreading force to ensure the restrictor ropes remained taut throughout each

tow. Each trawl used the NEFSC standard 36.6m bridles. All tows followed the NEFSC standard survey  
 towing protocols of 20 minutes at 3.0 knots. In 2015, 108 (45 day, 63 night) paired tows were conducted in  
 eastern Georges Bank and off of southern New England (Figure 3). In 2016, 117 (74 day, 43 night) paired  
 tows were conducted in western Gulf of Maine and northern edge of Georges Bank (Figure 4). In 2017, 103  
 (61 day, 42 night) paired tows were conducted in waters off of southern New England (Figure 5). Paired tows  
 were denoted as “day” and “night” by whether the sun was above or below the horizon at the time of the tow.  
 Winter flounder were caught in 171 paired tows (97 day, 74 night). Overall 6,449 winter flounder were  
 measured for length. The subsampling fractions implied an estimated 6,586 winter flounder were captured  
 across all paired tows. 3805 and 2644 length measurements were made for the chainsweep and rockhopper  
 gears, respectively. During the day, 2385 and 1220 winter flounder were measured in catches by the respective  
 gears whereas during the night 1420 and 1424 were measured in catches by the respective gears.  
 Windowpane flounder were caught in 195 paired tows (100 day, 95 night). Overall 13,014 windowpane were  
 measured for length. The subsampling fractions implied an estimated 15,310 windowpane were captured  
 across all paired tows. 9854 and 3160 length measurements were made for the chainsweep and rockhopper  
 gears, respectively. During the day, 5443 and 778 windowpane were measured in catches by the respective  
 gears whereas during the night 4411 and 2382 were measured in catches by the respective gears.  
 Red hake were caught in 73 paired tows (40 day, 33 night). Overall 12,585 red hake were measured for length.  
 The subsampling fractions implied an estimated 47,275 red hake were captured across all paired tows. 8587  
 and 3998 length measurements were made for the chainsweep and rockhopper gears, respectively. During the  
 day, 4908 and 1706 red hake were measured in catches by the respective gears whereas during the night 3679  
 and 2292 were measured in catches by the respective gears.

## 2.2 Paired-tow analysis

We use the hierarchical modeling approach from Miller (2013) to estimate the relative efficiency of chain  
 sweep to the rockhopper sweep used by the NEFSC bottom trawl survey for six species from three studies  
 carried out aboard a twin trawl vessel. Aside from the sweeps the rest of the trawl gear is the same. As in  
 Miller (2013), we compared a set of models with different assumptions about variation of relative efficiency  
 between paired gear tows, size effects on the relative efficiency, and extra-binomial variation of observations  
 within paired gear tows. We began with the same 13 models considered by Miller (2013). Models BI<sub>1</sub> to BI<sub>4</sub>  
 and BB<sub>1</sub> to BB<sub>8</sub> in Table ?? provides a descriptions of the models fitted for all species and pseudo-formulas  
 comparable to those used for fitting models in R and the mgcv package (Wood 2006; R Core Team 2019).

We then also included diel effects on relative catch efficiency and intereactions with size effects with the best performing model of the original 13 models for each species. For red hake, these are the same analyses provided in Miller et al. (2020) and the new analyses for winter and windowpane flounder are analogous. The analyses here and in Miller et al. (2020) are similar to those by Miller et al. (2017a), Miller et al. (2017b), and Miller et al. (2018), but a more generalized model has been implemented that allows multiple smooth effects on relative catch efficiency so that models do not have to be fit separately to observations occurring during the day and night. Therefore, diel effects on relative catch efficiency and interactions with size effects can be considered while allowing other parameters to be the same for all observations.

### 2.3 Length-weight analysis

We fit length-weight relationships to the length and weight observations for each survey each year. We assumed weight observation  $j$  from survey  $i$ , was log-normal distributed,

$$\log W_{ij} \sim N \left( \log \alpha_i + \beta_i \log L_{ij} - \frac{\sigma_i^2}{2}, \sigma_i^2 \right) \quad (1)$$

We used a bias correction to ensure the expected weight  $E(W_{ij}) = \alpha_i L_{ij}^{\beta_i}$ . We estimated parameters by maximizing the model likelihood programmed in TMB (Kristensen et al. 2016) and R (R Core Team 2019). Like the relative catch efficiency, bootstrap predictions of weight at length were made by sampling with replacement the length-weight observations within each annual survey and refitting the length-weight relationship to each of the bootstrap data sets.

### 2.4 Biomass estimation

We estimated biomass for each annual survey in terms of chainsweep efficiency by scaling the survey tow observations by the relative efficiency of the chainsweep and rockhopper sweep gears. First the tow-specific catches at length are rescaled,

$$\tilde{N}_{hi}(L) = N_{hi}(L) \hat{\rho}_i(L) \quad (2)$$

where  $N_{hi}(L)$  is the number at length  $L$  in tow  $i$  from stratum  $h$  and  $\hat{\rho}_i(L)$  is the relative efficiency of the chain sweep to rockhopper sweep at length  $L$  estimated from the twin trawl observations, that may depend on the diel characteristic of tow  $i$  if that factor is in the best model fitted to the twin-trawl observations. Note that we have omitted any subscripts denoting the year or survey.

110 The stratified abundance estimate is then calculated using the design-based estimator,

$$\hat{N}(L) = \sum_{h=1}^H \frac{A_h}{An_h} \sum_{i=1}^{n_h} \tilde{N}_{hi}(L) \quad (3)$$

111 where  $A_h$  is the area of stratum  $h$ ,  $A = \sum_{h=1}^H A_h$ , and  $n_h$  is the number of tows that were made in stratum  
112  $h$ . The corresponding biomass estimate is then

$$\hat{B} = \sum_{l=1}^{n_L} \hat{N}(L=l) \hat{w}(L=l) \quad (4)$$

113 where  $\hat{w}(L=l)$  is the estimated weight at length from fitting length-weight observations described above.  
114 Length is typically measured to the nearest cm so  $n_L$  indicates the number of 1 cm length categories that  
115 were observed during the survey.

116 To estimate uncertainty in biomass, we used bootstrap results for the relative catch efficiency and weight  
117 at length estimates along with bootstrap samples of the survey data. Bootstrap data sets for each of the  
118 annual surveys respected the stratified random designs by resampling with replacement within each stratum  
119 (Smith 1997). For each of the 1000 combined bootstraps, survey observations for bootstrap  $b$  were scaled with  
120 the corresponding bootstrap estimates of relative cookie sweep to rockhopper sweep efficiency and predicted  
121 weight at length, using Eqs. 3 and 4.

## 122 3 Results

### 123 3.1 Winter flounder

124 As measured by AIC, the best performing model for winter flounder before considering day/night effects was  
125 the conditional binomial model BI<sub>4</sub> (Table ??). Allowing smooth size-effects on relative catch efficiency and  
126 variation in these effects among paired-tows provided primary improvements in model performance. Including  
127 diel effects on relative efficiency for the twin-trawl observations improved performance of the binomial model  
128 (BI<sub>5</sub>), however the model allowing the size effects on relative efficiency to differ between day and night (BI<sub>6</sub>)  
129 would not converge. The relative efficiency of the chain sweep gear to the rockhopper sweep gear is greatest at  
130 the smallest sizes of winter flounder, but is fairly constant over sizes greater than 25 cm. The minimum  
131 relative efficiency is between 1.5 and 2 during the day, but efficiencies of the two sweeps are approximately  
132 equal efficiency at night (Figure ??).

Stock-specific biomass estimates from 2009 to 2019 for the NEFSC spring and fall survey were variable. Georges Bank winter flounder biomass estimates range between 1800 and 9400 mt in the spring and 3000 and 24,000 mt in the fall and are lower in recent years than those in the early years (Figure ?? and Table ??). However, we note that the estimates of biomass made here were determined in the 2019 assessment to be problematic because of the larger sizes that predominate in the Georges Bank stock area than other stock areas and the low number of observations in the chainsweep study of these larger individuals (NEFSC 2020). Gulf of Maine winter flounder biomass estimates are constrained to the segment of the population at least 30 cm in length. The spring biomass estimates have been fairly stable ranging between 900 and 2700 mt whereas the fall estimates were greater at the beginning of the time series than recent years and range between 1900 and 4300 mt (Figure ?? and Table ??). Southern New England winter flounder biomass estimates are also lower in recent years than the beginning of the time series for both seasons and spring and fall estimates range from 1300 to 8500 mt and 2100 to 47,500 mt, respectively (Figure ?? and Table ??).

The efficiency of the rockhopper gear relative to the chainsweep in terms of biomass changes from year to year due primarily to corresponding changes in the estimated numbers at length (Table ??). Annual biomass relative efficiency for Georges Bank winter flounder varied between 0.55 and 0.79 in the spring and 0.61 and 0.92 in the fall. Relative efficiencies for the Gulf of Maine stock range between 0.54 and 0.70 for the spring and 0.63 and 0.88 in the fall. Relative efficiencies for the Southern New England stock range between 0.64 and 0.91 for the spring and 0.60 and 1.0 for the fall.

Because the length-weight relationship which is used with the numbers at length to estimate biomass is estimated by survey and year there is a possibility that poor sampling in a given year could adversely affect the biomass estimates. We therefore calculated the ratios of the annual uncalibrated biomass estimates using just the aggregate catch data to the biomass estimates made using the numbers at length and estimated weight at length (i.e., Eqs. 3 and 4 without the relative efficiency at size). These ratios should be approximately 1. The ratios for all years and seasons for all three stocks of winter flounder varied from 0.94 to 1.04 (Table ??).

## 3.2 Windowpane flounder

As measured by AIC, the best performing model for windowpane flounder before considering day/night effects was the conditional binomial model  $BI_4$  (Table ??). Allowing smooth size-effects on relative catch efficiency and variation in these effects among paired-tows provided primary improvements in model performance. Including diel effects on relative efficiency at size for the twin-trawl observations improved performance of the binomial model ( $BI_6$ ). The relative efficiency of the chain sweep gear to the rockhopper sweep gear decreases

with size of windowpane flounder. The minimum relative efficiency is between 4.5 and 21 during the day, and between 1.8 and 2.9 at night (Figure ??).

Stock-specific biomass estimates from 2009 to 2019 for the NEFSC spring and fall survey were variable. Georges Bank-Gulf of Maine windowpane flounder biomass estimates range between 3000 and 20,300 mt in the spring and 4700 and 18,300 mt in the fall and are lower in recent years than those in the early years (Figure ?? and Table ??). Southern New England-Mid-Atlantic Bight windowpane flounder biomass estimates in the spring ranged between 7300 and 15,600 mt whereas the fall estimates ranged between 7300 and 14,700 mt (Figure ?? and Table ??).

The efficiency of the rockhopper gear relative to the chainsweep in terms of biomass changes from year to year due primarily to corresponding changes in the estimated numbers at length (Table ??). Annual biomass relative efficiency for Georges Bank-Gulf of Maine windowpane flounder varied between 0.21 and 0.36 in the spring and 0.19 and 0.42 in the fall. Relative efficiencies for the Southern New England-Mid-Atlantic Bight stock ranged between 0.22 and 0.36 for the spring and 0.26 and 0.35 in the fall.

Because the length-weight relationship which is used with the numbers at length to estimate biomass is estimated by survey and year there is a possibility that poor sampling in a given year could adversely affect the biomass estimates. We therefore calculated the ratios of the annual uncalibrated biomass estimates using just the aggregate catch data to the biomass estimates made using the numbers at length and estimated weight at length (i.e., Eqs. 3 and 4 without the relative efficiency at size). These ratios should be approximately 1. The ratios for all years and seasons for both stocks of windowpane flounder varied from 0.97 to 1.04 (Table ??).

### 3.3 Red hake

For red hake, the best performing model before considering day/night effects was the conditional beta-binomial model BB<sub>6</sub> (Table ??). The best beta-binomial model had an AIC more than 13 units lower than the best binomial model. Allowing variation in smooth size-effects on relative catch efficiency among paired-tows and extra-binomial variation withing paired-tows (overdispersion via the beta-binomial assumption) provided primary improvements in model performance. Including diel effects on relative efficiency for the twin-trawl observations improved performance of the beta-binomial model. Initially separate smooth size effects for day and night tows were considered for the beta-binomial model (BB<sub>8</sub>), but the correlation of non-smoother related random effects across stations was not estimable. Those random effects were therefore assumed uncorrelated (BB<sub>9</sub>). Allowing different smooth size effects of relative efficiency for day and night observations was considered (BB<sub>10</sub>), but it did not improve model performance. The relative efficiency of the chain sweep

gear to the rockhopper sweep gear generally declines with increased size whether the tow occurred during day or night, but the increase in efficiency of the chainsweep was generally greater for tows occurring during the day (Figure ??).

Stock-specific trends in annual biomass estimates from 2009 to 2019 for the NEFSC spring and fall survey were generally the same. For northern red hake both the spring and fall biomass estimates increased in 2014 and have remained higher than previous years (Figure ?? and Table ??). The scale of the biomass estimates is also similar for the spring and fall surveys. For southern red hake, the spring biomass generally declined until 2017 and then has increased for the last two years whereas the fall biomass has remained relatively stable (Figure ?? and Table ??).

The efficiency of the rockhopper gear relative to the chainsweep in terms of biomass changes from year to year due primarily to corresponding changes in the estimated numbers at length (Table ??). Annual biomass relative efficiency for northern red hake varied between 0.19 and 0.25 in the spring and 0.21 and 0.33 in the fall. Values range between 0.15 and 0.26 for the spring and 0.19 and 0.39 in the fall for southern red hake.

Because the length-weight relationship which is used with the numbers at length to estimate biomass is estimated by survey and year there is a possibility that poor sampling in a given year could adversely affect the biomass estimates. We therefore calculated the ratios of the annual uncalibrated biomass estimates using just the aggregate catch data to the biomass estimates made using the numbers at length and estimated weight at length (i.e., Eqs. 3 and 4 without the relative efficiency at size). These ratios should be approximately 1. The ratios for all years and seasons for both northern and southern red hake varied from 0.96 to 1.04 (Table ??).
